ABSTRACT

A distributed system’s functionality must continuously evolve, especially when environmental context changes. Such required evolution imposes unbearable complexity on system development. An alternative is to make systems able to self-adapt by opportunistically composing at runtime to generate systems of systems (SoSs) that offer value-added functionality. The success of such an approach calls for abstracting the heterogeneity of systems and enabling the programmatic construction of SoSs with minimal developer intervention. We propose a general ontology-based approach to describe distributed systems, seeking to achieve abstraction and enable runtime reasoning between systems. We also propose an architecture for systems that utilize such ontologies to enable systems to discover and “understand” each other, and potentially compose, all at runtime. We detail features of the ontology and the architecture through two contrasting case studies: one on controlling multiple systems in smart home environment, and another on the management of dynamic computing clusters. We also quantitatively evaluate the scalability and validity of our approach through experiments and simulations. Our approach enables system developers to focus on high-level SoS composition without being constrained by deployment-specific implementation details.

1 INTRODUCTION

Computing systems have evolved from the basic picture of connected PCs and mobile devices to the complicated picture of the inter-connected collections of heterogeneous systems. These systems include Internet of Things (IoT), clouds and micro-clouds, ad-hoc networks (MANETS, VANETS, FANETs), smart grids, among others. Each of these systems contains a set of heterogeneous components that implement diverse functions communicating using different protocols. Furthermore, these various systems often need to interact and collaborate to achieve their goals. For example, isolated rescue teams need to opportunistically compose and access each others services (e.g., data look-up) to exchange information; deployed environmental IoT systems process their data on a micro-cloud in their vicinity and offload certain processing to the cloud when needed; etc. In this sense, larger systems are constructed through the interaction of smaller ones, a practice known as System of Systems (SoS) composition or construction [21].

The inherent characteristics of SoSs make the development of these systems a challenging task [28]. By definition, a SoS is a complex system built from a (potentially large) number of sub-systems that in turn are made up of different components, and so on. Moreover, SoSs are typically deployed in environments where context changes. This is where the need arises to veer from a strict workflow path that has been defined at design time, and form a more complex system in order to maintain the intended abstract behavior or to be able to provide new behavior that is only possible through uniting with other systems in the new context. Such examples include disaster recovery, adaptive IoT applications, volunteer and crowd computing, military defense operations, and other forms of cyberphysical systems. Furthermore, the development of SoS is dynamic in nature. This is grounded in the knowledge that systems are persistent and long-living [30]. As such, their objectives and functionalities evolve over time as they are constantly added, modified, or removed at different time scales. This might also predicate changes in architectural and functional dependencies.

Despite the challenges posed by the above characteristics, current approaches of constructing SoSs assume that developers have in-depth knowledge of the internal structure of each system and its components [24]. Taking into account the above challenges and the characteristics of SoSs, it might be obvious that such approaches are deficient. We argue that the construction of SoS needs to be autonomous and dynamic. Systematic approaches for internal and context awareness are required to attain this goal. All systems should be able to accumulate knowledge about their own structure and behavior. Then, systems should exchange and be able to understand such knowledge at runtime so that they can opportunistically compose and form complex SoSs.
In order to achieve this objective, there is a need for semantics to comprehensively describe the system structure, capturing the information required for dynamically composing systems such as those relating to communication (e.g., unique identifiers), service discovery, quality of service, physical properties (e.g., power level and location), environmental properties, etc. We refer to this comprehensive structure description of a system as a holon [6]. A holon is constantly modified to reflect the system structure and to contain any new or modified information, and then published to aid discovery and reasoning about composition. When holons compose, they form a new holon that represents the SoS. This newly constructed holon will now have its own specification, which is published so that the system can further compose with other SoSs and so on.

The above holon ecosystem requires means of utilizing system (or holon) description in order to reason about SoS construction at runtime in a programmatic and adaptive manner. One solution is to adopt ontologies to specify the holons. Ontologies are engineering tools for formal and explicit specification of a shared conceptualization [10]. They provide vocabularies that can be used to represent knowledge that can be utilized programmatically to understand the corresponding contents, mainly system parameters, offered services, and requirements. These are expressed through standard concepts, allowing other holons to understand the described holon and, accordingly, make decisions about how to interact with it.

In [6] we proposed the vision towards the construction of distributed SoSs using holons, then in [29] we defined the basic conceptual structure with particular focus on IoT deployments. In this paper we build on these works by putting forward an architecture for realizing the holons and how they compose. The paper investigates how ontologies can be used to capture the holons’ space to enable autonomous SoS construction. Once specified, the holon description can be published through broadcasting to other systems. The description is compiled by receiving systems in order to understand the functionality of the sending system, reason about it, and determine how to communicate with it.

Briefly, the main contributions of this paper are as follows:

- A framework for specification, compilation, dissemination, and modification of the holons (§4–§6)
- A qualitative evaluation of the proposed approach using two different case studies that motivate the need for dynamic SoS construction and configuration (§7–§9).
- A quantitative evaluation of the scalability and validity of the proposed approach (§8, §10).

2 PROBLEM SPACE AND RELATED WORK

The SoS concept has featured in the literature for over two decades [21]. However, composing SoS from already existing systems at runtime is still an area that requires more research.

The significant body of work looking here is the Service Oriented Architecture (SOA) legacy. SOA allows a system to expose its functionalities as services, and then SOA composition technologies can be applied to form a SoS: cf. [3, 5, 42]. We argue that such SOA-based automation is not suitable for the following three main reasons. First, SOA does not readily provide concepts that capture physical system properties such as the context they are operating in. The service composition supported by SOA is mainly functionality-based composition. However, SoS composition is wider than this, as it also requires knowledge about system properties and context to reason about the composition. Second, services in SOA are assumed to be published in a repository that an orchestrator can consult to select services from. This assumption is not valid in the general SoS context which is fully distributed. Third, SOA-based SoS developers are expected to know a lot about individual systems, or invest significant time learning them. Fig. 1 illustrates the tasks performed by the vendors, developers, and the system for SoS composition. Developers are required to acquire knowledge about the APIs and properties of the elementary systems they need to compose. Then, they need to leverage that knowledge to design and implement the SoS, and finally deploy it. This requires the developer to focus on the elementary systems instead of the whole SoS.

Figure 1: Comparing the responsibilities in current SoS composition approaches and in the proposed one.

There has also been other non-SOA efforts. These include facilitating discovery and composition using cellular infrastructure [11] and network middleboxes [7]. Such approaches, though, require specific infrastructure deployment for mediation and, more importantly, still assume too much on the part of the developer in terms of reasoning about discovered systems. This final task is crucially difficult without means of identifying these systems’ modus operandi. Some works have chosen to do this at design time (e.g., [23]) through analyzing qualitative mission objectives of systems, but these are hard to express in a programmatic way that enables automated reasoning at runtime.

The closest work to ours also defines the notion of a holon [18, 32], but is focused on goal-driven service composition without means of allowing holons to reason about and self-compose.

Agent-based ontological approaches have been proposed, e.g., [1, 2, 12, 34]. However, these works are less systematic than our holon ontology. Moreover, they also do not indicate how composition is reasoned about in a heterogeneous environment.

3 RESEARCH STRATEGY

Based on the above, our ultimate goal is to shift the developers’ focus from learning the internals of elementary systems to thinking at the level of the SoS. As shown in Fig. 1, holons allow developers to focus on defining high-level workflows of the SoS. The elementary systems need to autonomously discover each other and compose to serve the requests. The achievement of this goal requires (1) a comprehensive description of the atomic systems (their services, properties, and context) that enable autonomous composition between systems; and (2) an architecture the exploits such descriptions and supports SoS composition and adaptation.
Our research seeks to answer the following three questions.

RQ1: What are the right abstractions to represent different systems within a SoS framework?
RQ2: What systems principles and techniques are then required to support SoS composition?
RQ3: What extensions are required to support SoS composition and adaptation in heterogeneous, large-scale environments?

Our work uses an ontological approach towards real-time reasoning around the composition of systems of systems. This is made possible by an architecture we have built for comprehending what an SoS is made up of, if composition is required, and how such composition would take place. Moreover, the architecture automatically actions the low-level mechanics that enable the composition. To validate the feasibility and utility of our architecture, we adopt a hybrid experimental evaluation strategy that comprises of qualitative assessment of controlled testbed experiments (specifically in the domains of IoT and infrastructure management) as well as quantitative assessment of real open-source systems.

4 THE HOLONIC LIFECYCLE

A holon starts as an atomic one then might evolve to being composite. An atomic holon represents a single system that provides one or more functionalities. A composite holon includes functionalities provided by a number of systems interacting with each other either directly or through others. In order for holons to compose, atomic holons need to be comprehensively specified by the system developer. After that, the system will be dynamically constructed as the holons iterate in their lifecycle. The four stages of a holon’s lifecycle (Fig. 2) are outlined below.

**Figure 2: A holon’s lifecycle**

**Specification.** A system developer uses an ontology to create the holon from a number of elementary descriptions. This includes a holon identifier, the physical properties of the system (e.g., power level), quality of service (e.g., availability and reliability), environmental properties (e.g., location), policies (e.g., routing protocol), services (e.g., sensing temperature), among others. All these are specified using our ontological model, described in §5.

**Dissemination.** A created holon disseminates its specification so it can be discovered. Different dissemination strategies can be adopted: push, pull, and lookup. In the push strategy, the holon periodically broadcasts its latest description. In contrast, a pull strategy uses heartbeat signals; i.e., the holon periodically sends ‘Hello’ messages to establish interaction with other systems, which could then request the full holon description. This strategy reduces overhead, so is useful in energy-constrained environments. In the lookup strategy, the holon registers its description with a registry that can be consulted by other systems to obtain the holon. This strategy is to be used when infrastructure assistance is guaranteed. We adopt the push strategy for the scope of this paper.

**Compilation.** This aims at understanding other holons and their functionalities. This is achieved by parsing received descriptions (in the form of XML representations), and identifying the functionalities contained within, and how they interact with that of the received holon. Compiling these functionalities into one holon representing a new SoS comprising of the interacting holons.

**Modification.** Holons can change at runtime due to a change in the physical system (e.g., update of a service) or due to a structural change (e.g., composition to a new holon). In either case, the holon description will be modified to reflect the change. Upon obtaining a modified version of a holon, the receiving holon will recompile its own holon and disseminate it. This will convey the changes to the whole SoS.

5 THE ONTOLOGICAL MODEL

5.1 Background

For a holon to be able to compose with another holon at runtime, it needs to advertise its own definition in a systematic way that can be easily understood by the receiving holon. For this, the definition needs to embody the different concepts surrounding the holon, triggering the need for an appropriate structure to represent it. In this respect, an ontology seems to be the best technique to capture the definition and behavior of a holon. An ontology is a formal and explicit specification of a shared conceptualization. It models some aspect of the world (called a domain), and provides a simplified view of certain phenomena in this domain. The description of the domain is based on a vocabulary that explicitly defines its concepts, properties, relations, functions, and constraints.

For our purposes, the ontology will be used by a holon to advertise its services, the types of input parameters required for said services, and the types of outputs they produce, if any. Furthermore, the ontology is used to identify the physical properties of the holon such as the power level (infinite/finite), location, operating system, mobility, etc.

Whilst an entirely new ontology can be developed from scratch, we deemed it more constructive to look at existing ontologies and extend suitable ones, i.e., the ones that contain the semantics required to describe holons, if and where necessary. In order to identify the most appropriate ontology to represent holons, we looked at different sensor and observation ontologies. We started with those surveyed by the W3C Semantic Sensor Network (SSN) Incubator Group [39]1, and continued with our own study of others. Table 1 shows the main ontologies that we reviewed.

Based on this investigation, the ontologies that we found suitable for extension are (in chronological order): CoDAMOS, Swano, A3ME, and Ontonym. We concluded to use CoDAMOS [31] due to its inherent predisposition for modification, making it easily extensible for defining context-aware computing infrastructures varying from small embedded devices to high-end service platforms. Furthermore, CoDAMOS’s concepts closely match the kind of definitions we want to create for a holon. For example, the Service concept - i.e., having a service profile - can be used to define the

---

1It should be noted that we did not specifically opt for the SSN ontology – despite it being a complete ontology about sensors and their measurements – as our focus is not limited to a sensor-based system, but is rather on capturing the abstract nature of a holon and on how to reason over whether a holon is atomic or composite.
types of services provided or required by a holon. Note, however, that this does not imply that the other shortlisted ontologies cannot be used. Indeed, A3ME [13] (to pick just one other ontology) could be merged with CoDAMOS to describe further concepts related to holonic design; for instance, the APIPublic CoDAMOS concept can be further described as GlobalAddress, LocalAddress, or OtherAddress using the Address concept of A3ME.

For this paper, we use CoDAMOS as the basis ontology with the aim of answering our research questions (§3), and in particular RQ1: is it possible to define something as abstract as a holon using an ontology, which is inherently prescriptive and unambiguous?

5.2 Extensions

Among its various concepts, there are four basic CoDAMOS concepts that stand out in terms of designing holons: User, Environment, Platform, and Service. The User concept has a profile, a role, and a task. The task can have activities and/or uses a service. The Environment concept defines a location (relative or absolute), a time, and an environmental condition (e.g., temperature, pressure, humidity, lighting, noise). The Platform concept has an Environment and can provide a Service (used by User). The Service concept has a profile, a model, and grounding. A Software concept links to Service through a property called providesService, and can be differentiated as middleware, VM, or OS. The Task concept makes use of a Service. Other resources such as memory, network, power or storage can also be modeled accordingly.

Fig. 3 summarizes how we extended CoDAMOS to accommodate the requirements of a holon. The Profile is extended to show profile preferences for routing messages in a system such as Ordering, Reliability and Delay. A new concept Node is added to capture the types of nodes encountered in a system: physical and abstract. This allows systems to be organized in a hierarchical way with physical systems at the very bottom of the hierarchy as leaf holons, and abstract systems as their parents, and so on till a root holon at the very top. All of these are added as concepts under the Holon concept. Furthermore, Service Properties has been extended to accommodate routing properties such as Delay, Reliability and Ordering. For implementing these extensions we used Protégé [25], an open-source ontology editor.

6 SOS CONSTRUCTION MODEL

This section provides the mechanics of using holonic ontologies in order to reason about their composition to form a SoS at runtime. At a high level, our approach is first to transform a holon to be represented by a weighted tree that reflects its interaction with other holons. Then, upon receiving a request for a service, the tree is used to find through which holon the service can be accessed. This section also presents the architecture that realizes the approach.

6.1 Composition model

Each holon needs to build a model that represents its awareness about the existence of other holons (i.e., systems) and their services. This model (called the composition model) is used to interact (compose) with the other systems by accessing their services. The composition model of a holon is represented as a weighted tree $T$ rooted by the holon and with a depth of three. The children of the root are the holons that are directly reachable by the root holon. The leaf nodes represent the detected functionalities that are provided by or accessed through the children holons. Each leaf node $i$ is assigned a weight that represents the cost of accessing
we define the cost as the distance between the root and the holon providing \( F_i \) in terms of the number of intermediate holons. Other cost functions such as delay, reliability or aggregated Quality of Service (QoS) can also be used. It is worth mentioning that a holon is not aware where a functionality \( F_i \) is located. However, the holon is aware of the cost of accessing \( F_i \) and through which holon \( F_i \) can be accessed. Fig. 4 shows an example of a holon connected to three other holons in its neighborhood. Functionality \( F_2 \) can be reached through both \( H_1 \) and \( H_2 \), but it is less costly to access through \( H_1 \).

**Figure 4: Composition/interaction modeling example.**

The composition model is frequently updated during the lifecycle of the holon. Updates include adding/removing new holon branches, and updating the services of current ones. Adding and updating are performed upon receiving holon ontologies, while removing is carried out if the ontology is not received during a certain time period (we set this to be three times the dissemination period).

### 6.2 Reasoning architecture

We assume that a system developer will create the atomic holon using the ontology described in §5. Once deployed, the holon lives in the described lifecycle (§4). Fig. 5 offers a high level view of the architecture that realizes SoS construction using the holonic approach. The architecture consists of five main components.

**Figure 5: System architecture**

**OWL parser.** This component receives ontologies from surrounding holons and parses them, creating objects that represent each holon and its functionalities. We adopt OWLAPI V5.1 [15] to parse ontologies and extract the knowledge therein.

Fig. 6 displays an overview of the mapping of ontology elements to a holon object. For each Class element, a Java class is created to represent it. For example, a Java class Service represents the ontology Service concept, Profile represents the Profile concept, and so on. The Instance elements of the ontology are instances of the Class elements. The instances are linked together using DataType or Object properties. Such structure is mapped as attribute objects of the Holon object. For example, assume the ontology contains an element service, that is an element of class Service. This instance can be linked to the Holon concept using an object property element called hasService. In the Java Holon class, this is mapped by having an attribute called service_1 of type Service in the Holon class. Finally, in the ontology Value elements represent some of the parameters values that are mapped as attribute values of the Holon Java objects. An example is the value ‘25°C’ of the Temperature element which is assigned to the temperature attribute in the Holon Java object. The OWL parser then passes the created Holon object to the Compiler.

**Compiler.** This component formulates a notional model of the developing SoS as seen from the perspective of the receiving holon. This model takes the form of a tree data structure with the receiving holon at the root, with each branch representing a neighboring holon and the functionalities provided either natively by it or indirectly through it. To construct or modify the tree, the Compiler creates a tree branch that represents the received holon object and its provided functionalists as children. The cost of each functionality is also updated as this stage. After that, the newly formed branch is attached to the root holon as a child. The Compiler then passes the constructed tree to the Server/Mediator and OWLRenderer.

**Server/Mediator.** This component receives requests for the functionalities provided by the system and serves them. It uses the constructed holon tree to specify whether the request can be satisfied by the system or needs to be directed to another holon. If the requested functionality is provided by the holon, then the system processes the request and responds to the requester. Otherwise, the system acts as a mediator and redirects the request to the holon that provides the request, waits for the response, and passes back the response to the requester.

**OWLRenderer.** What this component fundamentally does is represent the knowledge of a developing SoS based on interaction with new holons. The OWLRenderer reads the holon tree data structure from the Compiler and converts each node and the corresponding attributes into the appropriate XML tags that construct a valid ontology (i.e., an inverse mapping of Fig. 6). To render the ontology into an OWL description, we also use OWLAPI. Disseminator. Upon receiving an OWL description representing the holon and the compositions with other holons, the Disseminator publishes this description by broadcasting it as is the policy in the Push strategy (see §4).

### 7 CASE STUDY I: AUTONOMIC SMART HOME

In this case study, we focus on the ontology exchange between holons to realize SoS logic. The experimental context here is that of a smart home application that emerges as a SoS constituting a number of disparate IoT deployments.
7.1 Background and challenges

Smart Home is an application of IoT that promises the ability for users to intelligently manage their homes with minimum intervention. Devices are utilized to monitor home conditions (e.g., temperature, humidity) and the state of appliances (e.g., battery levels) to enable smart management of energy consumption, security, and various house keeping functions. However, it is no longer realistic to assume a defined and small scale of smart home deployments. As smart home systems are increasing in popularity, the dimensionality of IoT devices used is increasing as new devices are constantly offered in the market and with increased capabilities [40]. Thus, their deployment environments are continually evolving [38], making self-adaptation a necessity [16, 24].

Furthermore, homogeneity cannot be taken for granted [41]. The fact that these devices are developed by various vendors means that heterogeneous technologies and APIs exist. Smart home application developers need to learn these various technologies and APIs in order to develop IoT applications that manage the different aspects of a smart home in a coherent manner.

Finally, IoT applications generally limit consumers to the predetermined deployment environments they were designed for [27]. Consequently, they are brittle and susceptible to suboptimal operation when their context changes, e.g., due to a backhaul network fault or a server outage. Under such conditions, centralized (mainly cloud-based) approaches fall short especially in network-constrained conditions [8]. Instead, IoT applications often need a way to be able to adapt at the edge without preparation or central coordination.

7.2 Overview of our approach

In this case study, we illustrate how the adoption of our ontology-based approach helps to significantly mitigate the mentioned complexity. Building on the approach of integrating web services with the IoT technology to enable remote access of data gathered by the IoT devices (e.g., [33]), we argue that our approach enables the automatic discovery of services that are required for an adaptive smart home management application. As in the web service composition case, application developers need to specify the abstract workflow of the application execution where each task in the workflow represents an abstract service. Then, concrete implementations of the abstract services are selected for the workflow realization.

We consider each device as a holon that is described using the ontology (probably by the vendor). The management application is also considered as a holon that receives other holon ontologies, parses and compiles them, and then uses their services. Application developers specify the abstract workflow of the smart home management application. Then, the Server/Mediator component selects the concrete services that implement the abstract services of the workflow. A concrete workflow (the application) is passed to an execution unit that executes the application and passes the results to the smart home actuators. Fig. 7 illustrates the above steps.

7.3 Experimental setup

We developed a proof of concept prototype focused on smart home temperature management. We assume a smart home that has the following smart devices: heaters, thermometers, windows, and a fridge. The devices provide the services listed in Table 2.

<table>
<thead>
<tr>
<th>Device</th>
<th>Service</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Window</td>
<td>openWindows</td>
<td>Opens the windows (by actuators)</td>
</tr>
<tr>

</tr>
<tr>
<td>Fridge</td>
<td>replaceFilter</td>
<td>Tells if the filter should be replaced</td>
</tr>
<tr>
<td></td>
<td>foodLevelLow</td>
<td>Returns true if food level is low</td>
</tr>
</tbody>
</table>

We created a simple ontology for each of the devices as shown in Fig. 8. We also created an abstract workflow that aims at keeping the smart home temperature at 22°C, which is depicted in Fig. 9. The application reads the temperature from the thermometers. If the temperature is less than 22°C, it calls the heaters’ switchHeaterOn service to switch on the heating and the windows’ closeWindows to close the windows. If the temperature is higher than 22°C, it turns off the heater (calling switchHeaterOff). If the temperature is higher than 22°C it also opens the windows (by calling openWindows).

7.4 Behavior

Fig. 10 shows a snapshot of the controller ontology after parsing the device ontologies and constructing the SoS tree. The ontology
An Ontological Architecture for Principled and Automated System of Systems Composition

8.2 Overview of our approach

Both of the above restrictions can be overcome using the holonic ontology, which offers opportunistic composition (overcoming the first restriction) and horizontal composition between self-describing clusters in the form of holons (second restriction). We draw a scenario here to demonstrate this using containers running over an unreliable infrastructure such as edge PoPs [9]. In this scenario, each node can be a Master or an Agent. Following the basic design of Mesos, Masters are responsible for dispatching containers to the Agents, who in turn operate the containers.

8.3 Experimental setup

A simple example is given here to illustrate how holons could be used to facilitate the union of Mesos clusters with mobile nodes without the need for establishing direct communication. Due to the high mobility of nodes during the tests, the composition of SoSs is dynamic, creating several additions and removals of the Mesos Services. This is something that would have been prohibitive to accomplish using Mesos’ manual configuration.

We tested this use case study using 100 devices that can move freely. Every device is considered a node for Mesos and is individually defined as a holon at the beginning of the experiment. Shortly afterwards (a minute later), bigger holons begin to be created, containing one or more devices. After that, each holon starts an internal process of randomized leader election [26] to elect a master from amongst the constituent devices.

Each holon contains parameters to define its identifier, mobility, and whether or not it is a Mesos Master (e.g., Fig. 11). Additionally, each holon contains three services: AskForMaster is performed every time two holons reach each other for the first time, where it would return the ID of the Master. After a holon receives the request of whom is its Master, it will perform the SendToMaster service to send such ID. BridgeToMaster is used by the nodes to communicate with the Master through its Agents. Fig. 12 shows an abstract workflow of the experiment when a node reaches a

</tr>
</tbody>
</table>

shows that the controller provides services that are provided by the devices themselves (see Fig. 8) in addition to servicesSelector, which selects concrete services for the abstract workflow.

The execution starts with reading the temperature from the thermometer by calling the getTemperature service. Table 3 presents the experimental cases and the invoked cases for each case. As the table illustrates, the sequence of invoked services complies with the abstract workflow provided by the developer to the controller, despite the developer not hard-coding the required connections between devices. For example, when the temperature is 22°C, the execution unit invokes the getTemperature, switchHeaterOff, and closeWindows services respectively, which complies with the abstract workflow (Fig. 9).

This case study demonstrates the potential for easing the development of IoT applications, where application developers do not need to know the details of smart device APIs. Definition of device ontologies (by vendors) and an abstract application workflow (by smart home developer) are sufficient for runtime application synthesis and execution by the proposed architecture. Table 4 compares the tasks required from the smart home developers to implement this case study in both the classical and holonic approaches.

8 CASE STUDY II: DYNAMIC CLUSTER MANAGEMENT

In this case study we center our attention on holon interaction. We demonstrate how holons of similar ontologies (i.e., containing the same services) and that are in constant movement can interact with each other despite continuous creation and modification of new SoSs. Our context here is cluster management using Apache Mesos.

8.1 Background and challenges

Inspired by heterogeneous fog clusters, we set a scenario where device interaction is constant. We use Apache Mesos [14], an orchestration tool commonly used to manage resources that are shared between different applications and their sub-tasks. In effect, Mesos enables the viewing of data centers and other computing clusters as a single consolidated resource.

Although Mesos is a very useful utility, it was designed mainly for shared resources in relatively stable environments such as data centers. As such, the computing cluster can only change (i.e., grow or shrink) through manual modifications to the configuration by the user. Mesos was not designed to work in an environment where node status is constant flux due to movement, unreliable power, or communication outages. These are typical challenges in fog computing [35, 37]. Mesos is also designed to work in a hierarchical fashion, whereby Agents (worker nodes) can only communicate directly to the Master but not through other Agents [14, 17].

8.2 Overview of our approach

Both of the above restrictions can be overcome using the holonic ontology, which offers opportunistic composition (overcoming the first restriction) and horizontal composition between self-describing clusters in the form of holons (second restriction). We draw a scenario here to demonstrate this using containers running over an unreliable infrastructure such as edge PoPs [9]. In this scenario, each node can be a Master or an Agent. Following the basic design of Mesos, Masters are responsible for dispatching containers to the Agents, who in turn operate the containers.
new node from another Mesos cluster. A second abstract workflow has been created when a node receives a new ontology, which is depicted in Fig. 13. Both abstract workflows are used by the nodes to allow dynamic union of Mesos clusters with mobile nodes.

8.4 Behavior

Fig. 14a presents the starting point with holons \( H_1 \) and \( H_2. \) \( H_1 \) is formed of four nodes: nodeA, working as a Master, while nodeB, nodeC and nodeD as Agents. On the other hand, \( H_2 \) is formed of two nodes: nodeE, a Master, and nodeE, an Agent. In this case, \( H_1 \) and \( H_2 \) cannot reach each other.

As nodeC and nodeE come in range of one another (Fig. 14b), they are triggered to exchange ontologies and call askForMaster and subsequently SendMaster. The orange arrow in the figure represents this interaction.

Then, nodeC and nodeE broadcast their new ontologies to neighbors (Fig. 14c). Now, \( H_1 \) and \( H_2 \) are not just in contact with each other, they are part of a new super-holon \( H_3 \) which is the union of \( H_1 \) and \( H_2 \) as all their nodes receive the updated ontology and adopt it as their new ontology.

All Agents are sharing the Masters nodeA (from \( H_1 \)) and nodeF (from \( H_2 \)). This is achieved using the service BridgeToMaster, performed continuously by nodeC and nodeE while they can reach each other. The resulting SoS \( H_3 \) has 2 Master nodes and 4 Agents. Therefore, each of the two Masters can communicate to all Agents in \( H_3 \) as if they were connected directly. Similarly, this approach is also able to deal with Master mobility as long as the basic structure of a Mesos cluster is not broken down.

As such, the ontological exchange and reasoning of holons allows Apache Mesos to transcend its innate design shortcomings and enables it to form a dynamic cluster structure. Achieving such structure through manual configuration (which is the only way possible using native Mesos) significantly restricts adaptation and reduces cluster efficiency by a factor of 5 compared to using holons. Table 5 compares the tasks required from Mesos developers to implement the dynamic cluster management case study.

### Table 5: Tasks required from Mesos developers to implement the dynamic cluster management case study.

For evaluating the efficacy of automated expansion of Mesos clusters through the use of holon ontologies, we used the Omnet++ discrete-event simulation framework [36] to simulate 100 nodes. We set the node transmission range to 20m and their speed to 1.43m/s, an average walking speed [20]. Additionally, the nodes used the individual-level (random walks) [4] as a mobility model.

We used Mesosaurus [22] to create task loads to test the performance of the formed clusters. Specifically, we seek the length of...
The presented architecture exploits the holonic ontology and maintains the holonic lifecycle to fully support the vision of autonomous SoS composition and adaptation presented in this paper. The architecture continuously updates the holonic ontology allowing up-to-date SoS state exchange and enables timely response to changes. This allows holons to detect failures and discover new functionalities a holon needs to rebuild a SoS. As demonstrated in the cluster management case study ($\S$8), adaptation is fully autonomous. The system can, for example, detect the arrival of new working nodes and add them to the cluster.

Furthermore, human involvement is only needed when major requirements changes are required, i.e., at the SoS level. For example, a change in the smart home requirements that demands the deployment of new devices might require updating the behavior of the smart home applications, i.e., developers need to adapt the abstract workflows. However, such intervention is guaranteed to be minimal as developers do not need to know the low-level details of post-deployment systems such as device-specific APIs. Therefore, our proposed architecture provides a generic framework for supporting high-level behavior adaptation to real implementation.

10 QUANTITATIVE EVALUATION

As mentioned, our proposed framework includes means of parsing holon ontologies to build a tree that represents SoS construction, and subsequently rendering the tree to disseminate the modified ontologies that reflect SoS evolution. We conducted experiments to
evaluate the feasibility and correctness of this approach. Specifically, we investigate the time required to parse and render the ontologies at different scales, and we assess the validity of these stages. From this, we extract conclusions about the ability of using holons to compose SoS during runtime and at scale. The platform used in the experiments is Intel Core i7 with 16GB RAM, running Linux Ubuntu 16.04 and Java SE v1.8.0. Results shown are the mean values from 100 experiment repetitions.

10.1 Parsing
This first experiment focuses on evaluating the parsing time defined as the time of converting a received ontology into a tree (§6). Recall that that the tree contains the holon object as a root and the services provided by/via it as children. So, we vary the number of children (i.e., services) as the main dimension affecting parsing scalability. In Fig. 16a, we observe that parsing time increases linearly with the number of services, amounting to $< 0.35s$ for a very complex SoS that provides 1,000 services either directly or indirectly. We find this level of complexity to be acceptable, as it indicates the feasibility of parsing an increasing number of holons in a SoS.

10.2 Rendering
We now evaluate the rendering time defined as the time to convert a holon tree into an ontology to be disseminated. We vary both the number of neighbor holons (children) and the number of their services (leaves). The plot in Fig. 16b demonstrates that the rendering overhead increases both with the number of holons and the number of services per holon. This is acceptable for SoSs with up to 100 services per holon, where rendering overhead is $\approx 5s$. However this quickly inflates for holons with 1,000 or more sub-systems, where it could take up to a minute to create an ontology that could be used for composition.

10.3 Validation
In this subsection, we validate the output of the parsing and rendering operations using two experiments.

In the first experiment we adopt the process depicted in Fig. 17a. We create ontologies for 100 holons with random values for each of their parameter and service values. We then pass the ontology files to the OWLParser, which creates the holon trees. The trees are then passed to the OWLRenderer to render them into ontologies.

Figure 17: Our two methods to validate ontology parsing and rendering experiments. Parsing and rendering are deemed valid when the information returned by the queries match.

We then query (using OWLAPI) both the created ontologies and the rendered ones to check if the results are equivalent. For all 100 ontologies, the returned values were indeed equivalent.

In the second experiment, we adopt the process portrayed in Fig. 17b. Here, we synthesized 100 compiled trees, each representing a SoS. We then passed the trees to the OWLRenderer to render them into a SoS ontology for each tree. Then we queried both the rendered ontologies and the created trees to compare the results. Again, for all of the 100 cases, the returned values were equal.

11 CONCLUSION
We propose an approach for the dynamic construction of distributed systems of systems (SoSs). The approach is based on two key ideas. First, we define the concept of a holon as a self-describing system, which could span from atomic to complex distributed systems. Holons need to be prepared for autonomic integration with other holons. This is achieved by comprehensively describing them using an ontology that enables both self-awareness and context-awareness. Second, an architecture for SoS construction is proposed to make use of the holon description to discover, reason about their functionalities, and integrate them to form more complex SoS.

We demonstrate the feasibility of our approach through two case studies that implement contrasting SoS construction scenarios. The cases studies show that our approach reduces the development complexity of SoS by abstracting system heterogeneity using holon descriptions and their autonomic manipulation at runtime. We also evaluate scalability and validity through experimentation, concluding that our approach is realistically feasible with performance exhibiting a linear trend for manipulating and reasoning about descriptions.

This novel contribution has strong potential to be applied in various application fields beyond those covered in our case studies. Similarly, our architecture could be modified to cater for domain-specific interactions if particular situational-awareness are needed. Moreover, we are extending this work by building tools that allow very high level specification of desired SoS construction behavior and evolution.
